Abstract

Alzheimer's Disease (AD) poses a significant public health challenge due to its irreversible and progressive nature while lack of a cure. As a potential strategy to combat AD, its prevention becomes increasingly attractive. Mild Cognitive Impairment due to AD (MCI-AD) represents a critical transitional stage between normal age-related cognitive decline and more severe AD conditions, occurring just before dementia onset. Unfortunately, there is currently no established animal model that accurately recapitulates MCI-AD characteristics. While many laboratories have traditionally used normally aged wild-type animals as experimental models, this approach falls short in representing the inherently worse state of MCI-AD compared to normal aging. To address this gap, we introduce an animal model—a transgenic mouse line with genetic inactivation of G protein-coupled Receptor Kinase-5 (GRK5), commonly known as the GRK5 Knockout (GRK5KO) mouse. These GRK5KO mice exhibit amnesia, cognitive deficits, increased β -amyloid levels, Neurofibrillary Tangle (NFT) immunopositive axonopathy and hippocampal neurodegenerative changes. Importantly, these pathological alterations predominantly impact the entorhinal, trans entorhinal and hippocampal cortices, aligning with human MCI-AD criteria and Braak stage II of human AD progression. Notably, female GRK5KO mice show approximately 2.5 times more NFT-positive axonopathy than males, mirroring the higher prevalence of AD cases in women. Collectively, existing data strongly supports the GRK5KO mouse as a qualified animal model for studying MCI-AD.

Keywords: Alzheimer's disease; Mild cognitive impairment due to Alzheimer's disease; Aging; Animal model; GRK5 deficiency; GRK5 knockout mouse

Introduction

Alzheimer's Disease (AD) is the predominant cause of dementia, accounting for 60%-80% of dementia cases [1]. It is characterized by progressive decline in memory and other cognitive abilities due to neurodegenerative changes. Currently, there are no known methods for reversing or curing this disease [2]. This makes proactive prevention the most effective strategy to combat AD [3]. In serving such a purpose, a clinical collection

of Mild Cognitive Impairment due to AD (MCI-AD) was identified, which represents the last chance to intervene before the onset of AD. This article briefly describes the characteristics of MCI-AD in humans and the evidence that G protein-coupled Receptor Kinase-5 (GRK5) Knockout (GRK5KO) mice mirror MCI-AD criteria.

Mild Cognitive Impairment due to Alzheimer's Disease

MCI was initially established to understand the characteristics of individuals in a presumed pre-AD condition, which represents a transitional stage between normal age-related cognitive decline and more severe conditions like AD [4,5]. MCI involves noticeable cognitive decline beyond what is expected for a person's age but does not meet the criteria for dementia. However, MCI encompasses a heterogeneous group of patients with varying etiologies. Its longitudinal development does not always progress to AD; some individuals develop other dementias, while others remain in the MCI stage or even revert to normal cognition. Only a small portion of MCI cases eventually progress to AD. To better identify the true "pre-AD" population for AD prevention, experts led by the National Institute on Aging (NIA) and the Alzheimer's Association narrowed down MCI to a subgroup with a much higher tendency to develop AD down the road, terming this subgroup MCI due to AD (MCI-AD) [6,7].

To facilitate both clinical and laboratory research, specific clinical diagnostic criteria and research criteria were established for MCI-AD [6,8]. The clinical diagnostic criteria of MCI-AD were developed to aid clinicians in identifying MCI-AD without relying on invasive and more complex/expensive diagnostic tools such as imaging techniques. This condition is characterized by memory problems and cognitive issues, often serving as early indicators of potential progression to AD. The clinical diagnostic criteria for MCI-AD typically include:

Evidence of cognitive decline

There should be a noticeable decline in cognitive abilities, particularly in memory, exceeding what is expected for the individual's age but not severe enough to meet criteria for dementia.

Objective cognitive impairment

Objective evidence, usually obtained through cognitive assessments and standardized tests, indicates impairment in one or more cognitive domains.

Preserved independence in functional abilities

Individuals with MCI generally maintain their independence in daily functioning and do not meet the criteria for dementia, which involves a significant impact on daily activities. These criteria help distinguish MCI from normal age-related cognitive changes and more severe forms of cognitive impairment. The distinction between MCI and AD lies in the severity and impact on daily functioning. In MCI, individuals may experience cognitive challenges, especially in memory, but their overall functional abilities remain largely intact. The cognitive decline is noticeable but not severe enough to significantly interfere with daily activities. This intermediate stage allows healthcare professionals to identify potential early signs of AD or another type of dementia. If there is significant cognitive decline impairing daily functioning, a diagnosis of AD or another form of dementia may be considered.

From a research perspective, MCI-AD requires amnesia and at least another domain of cognitive decline, as well as evidence of concurrent AD pathogenesis [6,7]. Amnesia is essential, but research indicates that having another domain of cognitive impairment significantly increases the odds of developing AD in the future. Individuals with MCI-AD often exhibit pathogenic changes associated with AD, including:

Amyloid-Beta (A β) plaques

If MCI patients show an accumulation of A β or Senile Plaques (SPs) in the brain, a hallmark characteristic of AD, they are rated as A⁺ according to the ATN system [9,10].

Tauopathy

Elevated levels of Hyperphosphorylated Tau (pTau) protein, typically forming Neurofibrillary Tangles (NFTs). This is another hallmark characteristic of AD and is regarded as T⁺ in the ATN system.

Neurodegeneration

Structural brain changes and neuronal loss may be present in specific regions associated with memory and cognition, indicating neurodegeneration and is regarded as N⁺ per the ATN system. These changes contribute to the progression from MCI to AD. However, not everyone with MCI goes on to develop AD and the rate of progression varies among individuals. Having at least one or two AD characteristic changes in the ATN system is essential for MCI-AD, with more ATN positives indicating a higher likelihood of developing AD. Therefore, the pathogenic subtypes of MCI-AD include A⁺T⁻N⁻, A⁺T⁺N⁻, A⁻T⁺N⁻ and A⁺T⁺N⁺, with the latter representing the latest stage, right on the verge of AD onset [11-14].

In MCI-AD, certain brain areas associated with memory and cognitive function are often affected, including the hippocampus, entorhinal cortex, temporal lobes and prefrontal cortex. The specific areas affected can vary between individuals and the progression of structural changes may influence the severity and type of cognitive impairment observed. Neuroimaging techniques, such as Magnetic Resonance Imaging (MRI) or Positron Emission Tomography (PET) scans, help researchers and clinicians visualize these changes in the brain. Studies utilizing PET scans have indicated that MCI-AD corresponds to Braak stage II, primarily affecting the entorhinal, transentorhinal and hippocampal cortices [14].

Furthermore, brain inflammation or neuroinflammation, is recognized as a significant factor in AD progression. Evidence suggests the involvement of neuroinflammatory processes in MCI-AD, with increased levels of inflammatory markers observed in the brains of affected individuals [6,15]. Microglia, immune cells in the brain, play a role in the inflammatory response. However, the relationship between neuroinflammation and MCI is complex and not fully understood, though it is considered a part of the broader cascade of changes associated with AD progression, with heavier involvement in later stages.

MCI-AD is not a homogeneous condition and patients may exhibit variability in etiology and clinical presentation. However, commonalities exist among individuals diagnosed with MCI-AD, including underlying Alzheimer's pathology, memory impairment, neurological changes and cognitive decline beyond age expectations. Despite these commonalities, considerable heterogeneity exists in MCI cases, emphasizing the need for personalized approaches in understanding and managing this condition.

GRK5KO Mice-A Model of GRK5 Deficiency Recapitulates Characteristics of MCI-AD

GRK5 and its relevance to AD

Our comprehension of biological responses to *stimuli* exceeds that of their diminishing counterpart, desensitization. The latter involves a reduction in responsiveness to persistent *stimuli* while selectively engaging with new ones. G protein-coupled Receptor Kinases (GRKs) play a critical role in this process, particularly in signaling mediated by G Protein-Coupled Receptors (GPCRs), which constitute the largest family of signal-transducing proteins [16]. Central to its role in uncoupling G proteins from their coupled GPCRs upon the receptor activation for turning off the GPCR signaling, this novel GPCR regulatory mechanism earned the Nobel Prize in Chemistry in 2012 for Dr. Robert Lefkowitz, who contributed to the discovery of most GRKs and arrestins [17,18].

Currently, seven members of GRKs are identified: GRK1 to GRK7 [19,20]. Among them, GRK5 stands out as a ubiquitously distributed member implicated in various physiological functions [19,21]. Its activity has been associated with age-related

ailments such as neoplastic, metabolic, neurodegenerative and cardiovascular diseases, including type 2 diabetes mellitus, cardiac hypertrophy, hypertension, Parkinson's disease and AD [22-30]. During aging, dysfunction of the insulinotropic signaling cascade, affecting glucose sensing, uptake and metabolism, plays a pivotal role in aging across animal models [31]. The insulinotropic/insulin-like growth factor system primarily controls animal longevity, with genes associated mainly with this system [32-53]. GRK5's potential role in aging is underscored by its strong expression in adipose tissues, suggesting its impact on the glycoregulatory system [32]. Studies in GRK5KO mice demonstrated significant insulin resistance and GRK5 genetic polymorphisms have been linked to type 2 diabetes mellitus and the efficacy of antidiabetic drugs [33,34]. Furthermore, studies in GRK5KO mice highlighted its importance in metabolism, showing decreased white adipose tissue mass, reduced adipogenic gene expression and impaired adipocyte differentiation on a high-fat diet [33,35]. Although human data on GRK5 and metabolism are limited, they suggest an association with apolipoprotein B levels and total LDL-cholesterol, emphasizing its role in cholesterol metabolism. In addition, NF- κ B regulates GRK5 expression, indicating a feed-forward loop between these two systems, characteristic of aging [36]. GRK5 emerges as a vital component in energy metabolism and chronic inflammation paradigms, both strongly linked to molecular aging pathologies and various human disorders [37]. These insights position GRK5 as a potential therapeutic target for age-related diseases such as cardiovascular disease, neurological disorders and metabolic disorders [19,21,38].

The relevance of GRK5 to AD research became evident when rapid loss of functional/membrane GRK5 due to A β exposure was identified [29]. Subsequently, brain GRK5 deficiency was observed in the prodromal stage of AD in CRND8 AD transgenic mice and human AD autopsy samples [17,29]. GRK5 down-regulation is associated with prolonged platelet-derived growth factor receptor- β signaling and treatments with gonadotropin-releasing hormone, thyroid stimulating hormone, morphine or lipopolysaccharide [39-43]. Because plasma membrane-bound GRK5 is considered the functional portion for its GPCR kinase activity, membrane GRK5 deficiency could occur due to reduced membrane-associated GRK5 levels, in addition to reduced overall GRK5 expression [17,29]. Physiologically active GRK5 primarily associates with the plasma membrane, where it can be anchored on the inside of the cell membrane by binding to Phosphatidylinositol-4,5-bisphosphate (PIP₂) and phosphoserine [16,19]. Conversely, in the cytosol, GRK5 tends to associate with Ca²⁺/Calmodulin and F-actins [16,19]. Therefore, the balance of binding force for GRK5 between membrane (*e.g.*, PIP₂) and cytosol (*e.g.*, Ca²⁺/Calmodulin) may be important to regulation of its functionality, transitioning between a GPCR kinase and a signaling molecule or even a transcriptional regulator in the cell nucleus [17]. For instance, in cultured cells, A β can cause rapid (within minutes) GRK5 membrane disassociation, leading to membrane GRK5 deficiency, while increased cytosolic GRK5 may participate in mediating A β -induced cellular signaling changes that often prime different cells to become more sensitive to many cellular stressors [29,44,45]. From this perspective, potential causes of GRK5 deficiency could be attributed to factors

like cellular stress, calcium imbalance, nutritional deficiencies (especially phospholipids) and aging [17,44-48]. The relatively high levels of normal GRK5 distribution in the earliest affected brain regions of AD, particularly the limbic system, along with A β -induced down-regulation of GRK5, implicate involvement of GRK5 deficiency in AD [49,50]. While relations of GRK dysfunction to A β -related AD pathogenesis are still under investigation, another interesting piece of evidence is that a single nucleotide polymorphism associated with a functional GRK5 variant (GRK5-Gln41Leu) appears to decrease GRK5 translocation from the membrane to the cytoplasm, reducing tau hyperphosphorylation and is associated with a lower risk of late-onset AD [51].

As pointed out by Kohout and Lefkowitz, the regulation of GPCRs by GRKs exhibits both selectivity and redundancy [19]. This redundancy allows GRKs to compensate for each other's loss without significantly impacting the overall efficiency of timely GPCR signaling attenuation. However, studies in individual GRK knockout mice have unequivocally shown selective regulation by GRKs *in vivo*. For example, mice deficient in GRK2, 3, 5 and 6 display impaired desensitization of adrenergic, odorant, muscarinic and dopaminergic receptors, respectively [52-55]. Moreover, GRK5 deficiency selectively affects muscarinic receptors, particularly the G_{i/o}-coupled M2 and M4 receptors, without impacting M1/M3/M5 or non-muscarinic receptors [19,38,52,56]. Importantly, this high selectivity is observed only *in vivo*, not *in vitro*, suggesting a potential influence of topographic GRK subtype expression *in vivo*. Furthermore, this selectivity is apparent only when GRK deficiency occurs without compensation. Specifically, the membrane-associated nature of GRK5 renders its levels in neuronal terminals, such as spines and synapses, highly sensitive to early neurodegenerative changes. This sensitivity arises because GRK5, synthesized in the cytosol, must be transported through neurites to neuronal terminals, while axonal transport deficiency is among the earliest neurodegenerative changes occurring in normal aging and early AD [57]. Consequently, disruptions in neurite transportation, including axonal transport, could negatively impact GRK5 levels in neuronal terminals, including synapses. Notably, brain GRK5 levels sharply decrease during aging in Wild-Type (WT) mice. If defective axonal transportation occurs during aging, upregulation of GRK5 in an attempt to counteract GRK5 deficiency may not rectify the deficiency in neuronal terminals. Instead, the overexpressed GRK5 could accumulate where it is not deficient, leading to locally upregulated GRK5. Such upregulation could affect a wide range of GPCRs crucial in cardiovascular disorders [16,19,58,59].

Aged GRK5KO mice recaptured MCI-AD characteristics

MCI-AD represents the last chance to intervene before the onset of AD [4-7]. A good animal model of MCI-AD will help the relevant prevention and therapeutic studies. Currently, many studies have used aged WT animals to model MCI-AD, which we know MCI-AD is a transitional stage between normal aging and AD. This means that a real MCI-AD condition should be significantly worse than normal aging. In another word, normal aging is not a good representation of MCI-AD. In

this regard, aged GRK5KO mice mirror the MCI-AD criteria much better than aged WT mice, which will be described in detail below.

Up to now, GRK5KO mice have been studied and analyzed by multiple groups including ours. Given our focus on the brain functionality, the existing data in the GRK5KO mice from our group are summarized below and schematically illustrated in **Figure 1**.

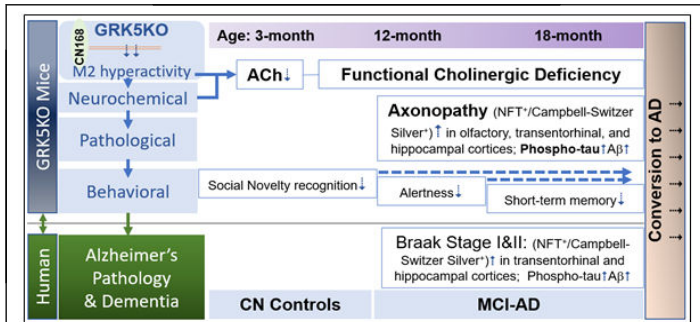

Figure 1: Schematic illustration of Age-dependent changes in GRK5KO mice. The age-dependent changes were illustrated as cholinergic hypofunction and impaired social novelty recognition without pathology at 3 months, impaired alertness/fear and mild axonopathy at 12 months and amnesia and moderate axonopathy at 18 months in GRK5KO mice. If the trend continues, the age-dependent changes may further develop in more advanced ages.

Behavioral assessment: The earliest indication of behavioral deficits in GRK5KO mice was reported in younger mice, aged 8-12 weeks, displaying impaired social novelty recognition by another group [60]. Our investigations unveiled a pattern of behavioral changes: From 12 months old, GRK5KO mice exhibit reduced travel distance in the open field without impaired sensorimotor function. By 18 months old, they manifest elevated time in the open arm of the elevated plus maze, indicating altered alertness and anxiety [30]. These observations coincided with the NFT⁺ axonopathy in the entorhinal and transentorhinal cortical regions at this age, revealing a connection between impaired behavior and neuropathology. A crucial cognitive deficit related to MCI-AD, amnesia, emerges at 18 months old, affecting spatial working memory in the Radial Arm Water Maze (RAWM) task but not the Y maze and Morris Water Maze (MWM) tasks, an implication of early-stage short-term memory deficit [30]. Although all the three tasks are able to measure short-term spatial memory different complexity of the setups allow them to detect the memory deficit with variable sensitivities (*i.e.*, more complicated 8-arms in RAWM may require more accurate spatial reference memory to succeed, therefore can detect earlier stage deficit) [61-63]. This was indeed supported by the actual data [30]. Overall, the 18-month-old GRK5KO mice exhibit amnesia and other cognitive impairments, fulfilling the behavioral criteria for MCI-AD.

Pathological assessment: The A/T/N system, introduced through the NIA-AA Alzheimer's diagnostic framework, serves as not only an impartial and descriptive classification approach for diagnosing and prognosing AD but also as a valuable tool for comprehending AD pathogenesis [9,10]. This stems from its

ability to condense AD pathogenesis into three primary categories of pathological alterations: A β , Tau and Neurodegeneration. This system offers a comprehensive and balanced assessment of pathological changes centered around AD. Hence, we present the pathological data in the GRK5KO mice by aligning them with the ATN system, enhancing clarity and while still able to acknowledge any distinctive features when necessary, such as the NFT⁺-axonopathy and cholinergic degeneration.

T⁺-related changes: The T⁺-related alterations in GRK5KO mice, up to 18 months of age, are both significant and represent one of the earliest and most pronounced pathological features. These changes were primarily identified through Campbell-Switzer (CS) Silver staining (which is sensitive to 3-repeats tau) and NFT immunostaining, revealing Swollen Axonal Clusters (SACs) [30]. The characterization of SACs was affirmed through axonal selective protein kinesin heavy chain immunostaining and electron microscopy (as presented in the original article) [30]. Interestingly, both KHC and NFT immunostaining demonstrated high sensitivity to the CS Silver positive SACs, reinforcing the T⁺ nature of these changes. Western Blotting corroborated these histological findings by showing a significant increase in pTau.

Notably, the temporal appearance of NFT⁺ axonopathy within the brain is particularly striking. It initially emerged in the olfactory region as early as 6-9 months old, subsequently in the piriform/amygdaloid regions and finally expanded into the hippocampus at mild level around 12 months and continued to accumulate. Remarkably, no such formations were detected in other cortical areas even at 18-months old. These characteristic T⁺ changes parallel those found in human AD brains at Braak stage I-II and correspond to the clinical stage of MCI-AD. These compelling data offer robust support for the involvement of GRK5 deficiency in MCI-AD.

A⁺-related changes: In 18-month-old GRK5KO mice, the A β -related alterations were identified as positive due to the presence of scattered SPs and an increase in SDS-soluble A β (sA β) though the SPs were immature at this stage, being primarily composed of fibrillary A β (fA β) encased by astrocytes without concurrent activation of microglial cells [30]. Additionally, notable inflammation was not globally evident at this point.

N⁺-related changes: In 18-month-old GRK5KO mice, while notable neurodegenerative alterations were observed, they were mild within the ATN system. No significant neuronal loss, either in total or specific to cholinergic neurons, was evidenced by quantification through stereology using NeuN or Choline Acetyltransferase (ChAT) immunostaining. However, an increase in hippocampal Cholinergic Axonal Swelling (CAS) was noted in the CA3 region and a decline in Cholinergic Fiber Density (CFD) was observed in the CA3 molecular layer and CA1 stratum oriens across the numerous brain sub regions investigated in GRK5KO mice. These findings collectively point to an early-stage cholinergic neurodegeneration.

Other pathological changes: The higher incidence of AD in female is a characteristic of AD [64-67]. Previous research from our group reported a 2.5-fold increase of the hippocampal Swollen Axonal Clusters (SACs) in female GRK5KO mice

compared to their male counterparts, which was aligned with such an AD characteristic, supporting the notion that gender differences in AD-related pathology are reflected in the GRK5KO mouse model [68]. In addition, we previously reported the cognitive evaluation of GRK5KO mice which the data was exclusively from female mice [30,69]. This decision stemmed from our initial characterization of GRK5KO mice, where statistical significance was not achieved from the male or mixed-gender groups although there was a trend [23,32]. For this reason, unless a study focus specifically requires consideration of gender differences, use of the female mice in experiments may maintain experimental consistency and avoid potential confounding factors related to gender variability.

In summary, GRK5KO mice developed progressive cognitive impairments including MCI-AD characteristic amnesia and other cognitive deficits up to 18 months [30,60]. Pathologically, they exhibited increased A β /SPs (A⁺), prominent CS silver staining and NFT immuno-positive axonopathy with increased pTau (T⁺) and reduced hippocampal cholinergic fiber density (CFD, \rightarrow N⁺), matching MCI-AD criteria and displaying characteristics of A⁺T⁺N⁺ MCI, a sub-variance of MCI-AD most likely to convert to AD [6,7,14,30]. Notably, NFT distribution in the olfactory, piriform, amygdaloid and hippocampus of GRK5KO mice aligned with the brain regional locations of the entorhinal (*i.e.*, olfactory) to transentorhinal (*i.e.*, piriform and amygdaloid) and hippocampal locations of the NFTs as defined in the Braak Stage II of human AD [11-14,30]. The latter coincides with the late stage of MCI-AD according to the recently developed positron emission tomography-based Braak staging [14]. On top of all the evidence, GRK5KO mice also displayed gender difference with the female having worsened pathology, that is an additional coincidence with AD. It is worth noting that all these changes in the GRK5KO mice were age-dependent development (as illustrated in **Figure 1**) and statistically significant as compared to the age-matched WT control mice. This indicates that GRK5KO mice recapture a disease stage between normal aging and AD and are more suitable to model MCI-AD than the aged WT mice [5,70]. Moreover, these GRK5KO changes replicated human MCI-AD features without altering any known AD genes or mutations, such as β -Amyloid Precursor Protein (APP), Presenilins, tau or ApoE. Therefore, the data collectively suggests that GRK5 deficiency may cause MCI-AD at least in mice.

GRK5 deficiency renders selective cholinergic neuronal vulnerability-a potential mechanism and therapeutical implication

The mechanisms underlying selective loss-of-function in GRK5 deficiency remain elusive, potentially tied to the distinct topographic expression patterns of various GRKs *in vivo* [19, 38]. Notably, presynaptic M2 hyperactivity could arise due to insufficient compensation by other GRKs at cholinergic synapses where GRK5 is deficient. Interestingly, this *in vivo* selectivity between GRKs and GPCRs is absent *in vitro*, suggesting that beyond chemical binding specificity, the specific spatial arrangement of GRK/GPCR pairs *in vivo* plays a crucial role. Consequently, upregulating GRK5 as a therapeutic strategy for GRK5 deficiency is ill-suited. Overexpression of GRK5, particularly

in cases of impaired axonal transport during aging and AD, may lead to mislocalization, ineffective compensation and broad impacts on various GPCRs, potentially elevating cardiovascular disease risks [16,19,58,59,71-73].

In the context of potential impacts of GRK5 deficiency in AD, studies have consistently demonstrated that GRK5 deficiency exacerbates AD progression in GRK5-deficient APP (GAP) mice. These impacts manifest as cognitive decline, increased amyloid burden and heightened inflammation [56,69,74,75]. Notably, in GAP mice, GRK5 deficiency accelerates Basal Forebrain (BF) cholinergic axonopathy and neuronal loss, leading to an earlier cognitive decline [69]. The underlying mechanism is believed to involve compromised cholinergic neuronal defense due to suppressed cAMP/CREB signaling. This signaling pathway plays a critical role in regulating the pro/anti-apoptotic threshold in cells [76-81]. Consequently, GRK5 deficiency selectively impairs presynaptic M2 receptor desensitization, resulting in presynaptic M2 hyperactivity [48,52,56]. The presynaptic M2 receptor is a Gi-coupled inhibitory receptor. While transient inhibition of M2 only reduces Acetylcholine (ACh) release [82-84], prolonged inhibition (from seconds to hours) suppresses the cAMP/CREB signaling pathway, ultimately lowering the cholinergic neuronal apoptotic threshold and rendering selective vulnerability in cholinergic neurons [56,69].

From a therapeutic perspective, directly overexpressing GRK5 may not necessarily compensate for the GRK5 deficiency. Instead, one way to rectify the impacts of GRK5 deficiency is to target the presynaptic M2 hyperactivity. In supporting this therapeutic implication, a recent investigation demonstrated that blocking the M2 receptor with a selective M2 antagonist CN168 in GAP mice effectively prevented BF cholinergic degenerative changes and successfully delayed cognitive decline for 5 months until the end of the experimental observations [85]. This study underscores the utility of this animal model for relevant prevention and therapeutic research.

It is noteworthy that CN168, a selective M2 antagonist, falls under the category of cholinergic modifying drugs, extensively investigated in AD research driven by the cholinergic hypothesis [86-89]. Notably, ChEIs, the most recognized cholinergic modifying drugs for AD, have been disappointing due to their limited efficacy in managing symptoms without modifying the disease course [90-92]. The fundamental difference between CN168 and ChEIs lies in their target mechanisms for addressing the underlying AD pathogenesis (see **Table 1** for comparisons between these two therapeutic strategies). ChEIs primarily focus on inhibiting cholinesterase to preserve Acetylcholine (ACh) levels in the synaptic cleft, mainly compensating for cholinergic hypofunction and alleviating associated symptoms [90]. In contrast, CN168 targets presynaptic M2 hyperactivity, preventing over-suppression of cAMP/PKA/CREB signaling in cholinergic neurons [38,69,93]. By strengthening the intrinsic defenses of these neurons, CN168 aims to enhance resilience against degenerative insults. Although CN168 may increase ACh release during its use, it was not administered during the cognitive tests in this study. In fact, the drug was withdrawn two weeks before the cognitive tests [85]. This experimental design eliminated any cognitive impact resulting from acute influences

on ACh release by the drug. If any, the cognitive tests were conducted during the drug withdrawal period, during which, in the case of ChEI discontinuation or withdrawal, worsening of symptoms might occur [94-97]. Thus, the improvements in to revolutionize our understanding of AD, shedding light on the mechanisms guiding MCI-to-AD transformation. Ultimately, we aspire to harness this model for effective pharmaceutical AD prevention, instilling hope for millions affected by this condition.

Table 1: Comparisons between the therapeutic strategies using CN168 versus ChEIs.

Treatment	CN168	ChEIs
Target system	Central cholinergic system	Central cholinergic system
Target position	Presynaptic	Postsynaptic
Target molecule	M2 autoreceptor	ACh
Direct effect	M2 inhibition	Cholinesterase inhibition
Acute impacts in the presence of the drug	Increased ACh release and revoked suppression of cAMP/PKA/CREB signaling	Delayed ACh degradation, prolonged ACh effects on all cholinergic receptors including M2 autoreceptor
Potential impacts on the cholinergic neurons	Strengthened cholinergic neuronal resilience and survival	Weakened cholinergic neuronal resilience potentially by enhancing the M2 hyperactivity
Impacts after the drug withdrawal	Cognitively normal	Potentially worsened symptoms
Disease modifying	Yes	No

cognition observed in this study were likely attributed to the preservation of cholinergic neurons rather than functional compensation for cholinergic hypofunction.

Conclusion

GRK5KO mice exhibited amnesia and other cognitive deficits, along with increased AD pathogenesis characterized as A⁺T⁺N⁺. These changes align with the criteria for human MCI-AD, qualifying for serving as an animal model for MCI-AD. Further exploration and utilization of this model will facilitate the efforts in understanding MCI to AD conversion and prevention.

Future Perspectives

The urgent need for effective AD prevention underscores the importance of understanding MCI-AD. GRK5KO mice faithfully replicate MCI-AD characteristics, addressing the unmet need for a suitable animal model. However, the precise roles of GRK5 deficiency in MCI and AD pathogenesis remain to be fully elucidated. The convergence of MCI-AD features across multiple levels cannot be attributed solely to coincidence; hidden logic and phenomena await discovery. Deeper and broader investigations into etiology and epidemiology may yield further evidence.

Immediate utilization of the GRK5KO model can be both mechanistic and therapeutic. By introducing risk factors, we can dissect critical drivers of MCI-AD conversion. Targeting known pathways (e.g., M2 blockade) may offer therapeutic or preventive implications. This research avenue has the potential
